Estimation of discrete-event systems

using interval computation

Abstract: Discrete-event systems are driven by events and generate events. To describe their evolution, the dater approach associate to each event a sequence of dates, namely a dater, corresponding to the dates at which the event occurs.

In this paper, we show that for a large class of discrete-event systems, the dater approach makes it possible to cast the characterization of the set of all parameters that are consistent with some collected dater, in a bounded-error context, into a set-inversion framework. Set inversion consists of characterizing the reciprocal image of a given set by a known function. Provided that an inclusion function is known for the function to be inverted, the characterization can be performed by the interval-based algorithm SIVIA. A short presentation of this algorithm is recalled in this paper. The approach is illustrated through three examples.

Keywords: Bounded-error estimation, discrete-event systems, interval analysis, set inversion.
I. Introduction

Many systems such as manufacturing, communication or transportation systems, are event-driven as opposed to time-driven, i.e., their behaviors are governed only by occurrences of different types of events rather than by ticks of a clock. For example, events can be: ’the machine has just completed its task’ or ’the traffic light changes to red’. Such systems are known as Discrete-Event Systems (DES), (see, e.g., [5], [12], and references therein) and are often described graphically by using Petri nets (see, e.g., [11]). When an event occurs, a process may start. When the process is finished, the event ’process ends’ yields. When the processing time is known for each process of the DES, the DES is a Timed Discrete Event System (TDES) (see, e.g., [3], [5] and [7]). Only TDES will be considered in this paper.

Among the approaches proposed in the literature to describe TDES by recurrent equations, let us quote :

- **the counter approach**: To each event of the TDES, is associated the integer \( k(t) \), which represents the number of occurrence of the event at time \( t \). The function \( k(t) \) is non decreasing and is called a **counter**.

- **the dater approach**: To an event, is associated the real \( x(n) \) which is the date at which the event occurs for the \( n \)th time. The sequence \( x(n) \) is non decreasing and is called a **dater**.

**Example 1**: A machine assemble two parts \( A \) and \( B \) in \( \delta \) seconds. The three events involved in our example are: \( e_A = \text{’a part } A \text{ arrives’}, e_B = \text{’a part } B \text{ arrives’} \) and \( e_Y = \text{’an assembling process ends’} \). Associated counters are denoted \( k_A(t), k_B(t), k_Y(t) \) and associated
daters \( x_A(n), x_B(n), x_Y(n) \), respectively. The counter and the dater equations are:

\[
\begin{align*}
    k_Y(t) &= \min(k_A(t-\delta), k_B(t-\delta), k_Y(t-\delta) + 1) \\
    x_Y(n) &= \max(x_A(n), x_B(n), x_Y(n-1)) + \delta
\end{align*}
\]

\( \diamond \)

In what follows, we shall only consider dater equations, but the approach can also be adapted to counters.

Considering a new definition for the additive and multiplicative operators \( (a \oplus b = \max(a, b) \) and \( a \otimes b = a + b \), timed event graphs (TEG) are TDES which can be described by the following \((\oplus, \otimes)\)-linear state equations (see [1]):

\[
\begin{align*}
    \bar{x}(n+1) &= A \otimes \bar{x}(n) \oplus B \otimes \bar{u}(n+1) \\
    \bar{y}(n) &= C \otimes \bar{x}(n)
\end{align*}
\]  

(1)

where \( \bar{x}(n) \) is a state vector and \( \bar{y}(n) \) is the vector of daters of interest. The system considered in Example 1 is a TEG because the dater equation can be written as

\[
\begin{align*}
    x(n+1) &= \delta \otimes \bar{x}(n) \oplus \left( \begin{array}{c}
        \delta \\
        \delta
    \end{array} \right) \otimes \begin{pmatrix}
        x_A(n+1) \\
        x_B(n+1)
    \end{pmatrix} \\
    x_Y(n) &= -\infty \otimes x(n).
\end{align*}
\]  

(2)

TEG are particularly suited to describe synchronization phenomena and because of their \((\oplus, \otimes)\)-linearity, powerful tools are available to deal with them (see, e.g., [2] for parameter estimation, [3] for resource optimization and [4] for control applications), but unfortunately, many TDES cannot be described by (1). Even nonlinear state space equations

\[
\begin{align*}
    \bar{x}(n+1) &= \bar{f}(\bar{x}(n), \bar{u}(n+1)) \\
    \bar{y}(n) &= \bar{g}(\bar{x}(n))
\end{align*}
\]  

(3)

cannot be used to describe TDES that are non causal with respect to \( n \). Indeed, for a system described by equation 3, \( \bar{y}(n) \) does not depend on \( \bar{u}(m) \) if \( m > n \) i.e. the system (3)
is causal. Unlike discrete time systems that can often be described by (3), many TDES are
noncausal because of the special nature of \( n \) as illustrated by the following example.

**Example 2:** A machine assembles two identical parts \( A \) in \( \delta \) seconds to produce a part \( B \).
The events involved are \( e_u = \) 'a part \( A \) arrives' and \( e_y = \) 'an assembling process ends'. If
\( u(n) \) is the input dater associated with \( e_u \) and \( y(n) \) the output dater associated with \( e_y \), we have

\[
y(n) = \max((u(2n), y(n - 1)) + \delta.
\]

for \( n \geq 1 \) and \( y(0) = -\infty \). Since \( y(n) \) depends of \( u(2n) \), the system is noncausal with
respect to \( n \). Therefore it cannot be described by (3).

For the sake of simplicity, dater sequences \( d(k) \) are assumed to be finite and are represented
by a sorted vector \( \vec{d} \). The \( k \)th component \( d_k \) of \( \vec{d} \) corresponds to \( d(k) \). Even if state space
equations (3) do not exist for a general TDES, it is often easy to express the output dater
vector \( \vec{y} \) with respect to the input dater vector \( \vec{u} \) as

\[
\vec{y} = f(\vec{u})
\]

where \( f \) is a discontinuous function that can be represented by an algorithm. Unfortunately,
the algorithm \( f \) may involve sorting procedure, if statements, \ldots and problems like

\[
\text{find } \vec{u} \text{ such that } f(\vec{u}) = \vec{y}
\]

cannot be solved using formal methods. Now, for a large class of functions \( f \) and for
reasonable dimensions of \( \vec{u} \), the resolution of (6) can be performed by using interval analysis
(see e.g. [6] and [9]).

To illustrate how interval analysis can be an efficient alternative to formal approaches when
dealing with TDES, we shall consider, in this paper, the estimation of some unknown para-
meters of a TDES, in a bounded-error context. If \( \vec{Y} \) denotes the known box of all feasible
output dater vectors, \( \bar{u} \) the known input dater vector, \( \bar{p} \) the unknown parameter vector and \( \tilde{f}(\bar{p}, \bar{u}) \) the model output dater vector, then the problem of interest is to characterize the set

\[
P = \{ \bar{p} | \tilde{f}(\bar{p}, \bar{u}) \in \tilde{Y} \},
\]

(7)

Since \( \bar{u} \) is known, \( \tilde{f}(\bar{p}, \bar{u}) \) will be denoted \( \tilde{f}(\bar{p}) \). The set to be characterized is thus defined by

\[
P = \tilde{f}^{-1}(\tilde{Y}).
\]

(8)

The problem to be solved is therefore a set inversion problem. The algorithm SIVIA (Set Inversion Via Interval Analysis, (see [8] and [10])) able to solve it, is presented in Section II, with some basic notions of interval analysis. Illustrative examples are finally treated in Section III.

II. INTERVAL ANALYSIS AND SET INVERSION

A. Notion of interval analysis

Interval analysis [9] is based on the notions of boxes and inclusion functions that are now introduced. A box or vector interval \( \tilde{X} \) of \( \mathbb{R}^n \) is denoted equally:

\[
\tilde{X} = ([x_1^-, x_1^+], \ldots, [x_n^-, x_n^+]) = (X_1, \ldots, X_n) = [\bar{x}^-, \bar{x}^+]
\]

(9)

where \( \bar{x}^- = (x_1^-, \ldots, x_n^-)^T \) and \( \bar{x}^+ = (x_1^+, \ldots, x_n^+)^T \). The set of all boxes of \( \mathbb{R}^n \) is denoted by \( \mathbb{R}^n \). A principal plane of a box \( \tilde{X} \) is a symmetry plane of \( \tilde{X} \) normal to a side of maximum length. To bisect a box \( \tilde{X} \) means to cut it along one of its principal planes. This operation generates two non-overlapping boxes \( \tilde{X}_1 \) and \( \tilde{X}_2 \) such that \( \tilde{X} = \tilde{X}_1 \cup \tilde{X}_2 \).

Let \( \tilde{f} \) be a vector function mapping \( \mathbb{R}^n \) into \( \mathbb{R}^m \). A set-valued function \( \tilde{F} \), defined from \( \mathbb{R}^n \) into \( \mathbb{R}^m \), is an inclusion function of \( \tilde{f} \) if:

\[
\forall \tilde{X} \in \mathbb{R}^n, \quad \tilde{f}(\tilde{X}) \subset \tilde{F}(\tilde{X}).
\]

(10)
Let $w(\bar{X})$ be the width of the box $\bar{X}$, i.e., the length of its largest side(s). An inclusion function is \textit{convergent} if, for any sequence of boxes $\bar{X}(k)$ of $\mathbb{R}^n$, 
\[
\lim_{k \to \infty} w(\bar{X}(k)) = 0 \implies \lim_{k \to \infty} w\left(\bar{F}(\bar{X}(k))\right) = 0. \tag{11}
\]

An inclusion function $\bar{F}^*$ for $\bar{f}$ is \textit{minimal} if, for all $\bar{X}$, $\bar{F}^*(\bar{X})$ is the smallest box that encloses the image set $\bar{f}(\bar{X})$. If $\bar{f}$ is a nondecreasing function, i.e., $\bar{x} \geq \bar{y} \implies \bar{f}(\bar{x}) \geq \bar{f}(\bar{y})$, where inequalities have to be understood componentwise, then a minimal inclusion function for $\bar{f}$ is given by [9]:
\[
\bar{F}^*(\bar{X}) = [\bar{f}(\bar{x}^-), \bar{f}(\bar{x}^+)]. \tag{12}
\]

Let us denote by $\bar{s}$ the sorting function mapping $\mathbb{R}^n$ into $\mathbb{R}^n$ defined by
\[
\bar{s}(x_1, x_2, \ldots, x_n) = (x_{i_1}, x_{i_2}, \ldots, x_{i_n}), \tag{13}
\]
where $\{i_1, \ldots, i_n\}$ is a permutation of $\{1, 2, \ldots, n\}$ such that $x_{i_a} \leq x_{i_b}$ if $a < b$. For example, $\bar{s}(5, 4, 7) = (4, 5, 7)$. The function $\bar{s}$ is nondecreasing, i.e., $\bar{x} \geq \bar{y} \implies \bar{s}(\bar{x}) \geq \bar{s}(\bar{y})$. The minimal inclusion function for $\bar{s}$ is therefore (see equation (12)) $\bar{S}(\bar{X}) = [\bar{s}(\bar{x}^-), \bar{s}(\bar{x}^+)]$. For example,
\[
\bar{S}([6, 9], [1, 7], [4, 5]) = [\bar{s}(6, 1, 4), \bar{s}(9, 7, 5)] = \tag{14}

[(1, 4, 6), (5, 7, 9)] = ([1, 5], [4, 7], [6, 9]) .
\]

B. Set inversion algorithm

The algorithm SIVIA [8],[10] able to characterize the solution set defined by (8) is now presented. Its principle is to partition the prior box of interest $\bar{P}_0$ into a set of non-overlapping boxes, namely those that are enclosed in $\mathcal{P}$ and those that are outside $\mathcal{P}$. A convergent inclusion function $\bar{F}$ associated with $\bar{f}$ is assumed to be available. The following tests make
it possible to decide whether a given box $\vec{P}$ is inside or outside the solution set $\mathcal{P}$:

\begin{align}
(i) \quad & \vec{F}(\vec{P}) \subset \vec{Y} \quad \Rightarrow \quad \vec{P} \subset \mathcal{P}, \\
(ii) \quad & \vec{F}(\vec{P}) \cap \vec{Y} = \emptyset \quad \Rightarrow \quad \vec{P} \cap \mathcal{P} = \emptyset.
\end{align}

SIVIA is a recursive routine that makes it possible to draw a bracketing of the solution set $\mathcal{P}$. Boxes that have been proved to belong to $\mathcal{P}$ via test (i) are painted grey, those that have been proved to be outside from $\mathcal{P}$ via test (ii) are painted white and those that satisfy neither (i) nor (ii) and that are too small ($< \varepsilon$) to be bisected are painted black. The first call of SIVIA is done by \texttt{SIVIA($\vec{P}_0$)}, where $\vec{P}_0$ is the prior feasible box for the parameter vector. The box $\vec{P}_0$ is assumed to be large enough to contain the solution set $\mathcal{P}$.

\begin{algorithm}
\caption{SIVIA($\vec{P}$)}
\begin{algorithmic}
\STATE \textbf{Step 1} If $\vec{F}(\vec{P}) \subset \vec{Y}$, \{draw(\vec{P}, 'grey'); return\};
\STATE \textbf{Step 2} If $\vec{F}(\vec{P}) \cap \vec{Y} = \emptyset$, \{draw(\vec{P}, 'white'); return\};
\STATE \textbf{Step 3} If $w(\vec{P}) < \varepsilon$, \{draw (\vec{P}, 'black'); return\};
\STATE \textbf{Step 4} Bisect $\vec{P}$ getting the two boxes $\vec{P}_1$ and $\vec{P}_2$;
\STATE \textbf{Step 5} SIVIA($\vec{P}_1$); SIVIA($\vec{P}_2$);
\end{algorithmic}
\end{algorithm}

\textbf{Remark 1} \quad If we denote by $\Delta \mathcal{P}$ the union of all boxes painted black and by $\mathcal{P}^-$ the union of all boxes painted grey, the solution set $\mathcal{P}$ is bracketed by [8]: $\mathcal{P}^- \subset \mathcal{P} \subset \mathcal{P}^- \cup \Delta \mathcal{P}$. $\diamond$

\textbf{Remark 2} \quad For the sake of simplicity, SIVIA has been presented as an algorithm for drawing a bracketing of a two-dimensional solution set, but it can also be used to characterize solution sets of higher dimensions [8]. $\diamond$

\textbf{Remark 3} \quad The set inverted by SIVIA is a box $\vec{Y}$ and the set to be inverted in our estimation problem is an interval data vector $\vec{Y}_D$. These two sets are not equal: for example, the sequence (or vector) $\vec{y} = \{3, 2\}$, which is not a data vector (non-increasing components) is inside the box $\vec{Y} = [1, 4] \times [2, 5]$, but does not belong to the interval data vector.
\( \tilde{Y}_D = [1, 4; 2, 3] \), because \( \tilde{Y}_D \) only contains vectors of \( Y \) with increasing components. Now, for any \( \tilde{\nu} \), the vector \( \bar{f}(\tilde{\nu}) \) is necessarily a daten vector because \( \bar{f} \) simulates a DES. Therefore inverting an interval daten vector or its corresponding box always yields the same set. \( \Diamond \)

III. Application to DES estimation

In this section, the behavior of SIVIA is illustrated through three test cases.

**Test case 1:** A machine manufactures parts located in an input stock. The input daten vector
\[
\hat{\nu} = (0, 0, 10, 13, 16, 17, 18, 25, 25, 30)^T
\] (16)
contains dates at which a part is given to the input stock. The loading of a part in the machine occurs when the machine is free and when a part to be manufactured is available.

The working time of the machine, assumed to be given by \( \delta(k) = p_1 + \ln(p_2 k + 1) \), where \( k \) is the number of manufactured parts, depends nonlinearly on \( p_2 \) and \( k \). This may correspond to a situation where the efficiency of the machine decreases as parts are proceeded. The output daten vector \( \check{\nu} \) contains dates at which the machine has just completed a part. The simulator function \( \bar{f}(\tilde{\nu}) \) is computed by the following algorithm:

Input: \( \tilde{\nu} \)

\[
\delta(1) := p_1 + \ln(p_2 + 1); \quad \bar{f}_1 := \delta(1) + u_1;
\]

For \( k := 2 \) to 10 do

\[
\{ \delta(k) := p_1 + \ln(p_2 k + 1); \\
\bar{f}_k := \bar{f}(k) + \max(\bar{f}_{k-1}, u_k); \}
\]

Output: \( \bar{f} \);

The daten vector of experimental data
\[
\check{\nu} = (1.7, 3.8, 12.4, 15.6, 18.8, 21.7, 24.8, 28.2, 31.5, 34.9)^T
\] (17)
has been obtained by considering \( \delta(k) := 1 + \ln(k+1) \), which corresponds to set \( p_1 = p_2 = 1 \).

A model output dater vector \( \bar{f}(\bar{p}) \) is assumed to be acceptable if for all \( k \), \( |\bar{f}_k(\bar{p}) - y_k| < 0.3 \), i.e., the output dater vector \( \bar{f}(\bar{p}) \) falls inside the box \( \bar{Y} = \bar{y} + 0.3[[-1, 1]]^{10} \), where \([[-1, 1]]^{10}\) denotes the ten-dimensional box whose components are equal to \([-1, 1]\). For the prior feasible box \( \bar{Y}_0 = ([0, 3], [0, 4]) \) and for \( \varepsilon = 0.01 \), SIVIA brackets the posterior feasible set \( \bar{P} \) for the parameters, as represented by Figure 1, in less than 10 seconds on a PC DX4-100 computer. Grey boxes are proved to be inside \( \bar{P} \) and white boxes are proved to be outside \( \bar{P} \). No conclusions have been reached for the black boxes.

**Possible location for Figure 1**

**Test case 2**: Let us consider a plane where ten acoustic transmitters are located at positions \((x_i, y_i)^T\) given by Table 1. Each transmitter emits an indiscernible impulse sound at date 0. A robot, whose position \( \bar{p} = (p_1, p_2)^T \) has to be estimated, is equipped with a sound sensor and records a dater vector \( \bar{y} \), the component of which corresponds to dates at which a sound is detected. It is assumed that ten dates have been recorded and stored into the output dater vector

\[
\bar{y} = (1, 2.24, 3.3, 6.4, 4.12, 4.47, 5, 5.1, 5.38, 6.4)^T.
\]  

(18)

The propagation delay associated with the \( i \)th transmitter is assumed to be proportional to the distance between the robot and the transmitter:

\[
\delta_i = \lambda \sqrt{(x_i - p_1)^2 + (y_i - p_2)^2}, \ i = 1, \ldots, 10.
\]

(19)

For the sake of simplicity, the constant \( \lambda \), related to the sound velocity, is assumed to be equal to 1. The set of all feasible dater vector is given by \( \bar{Y} = \bar{y} + [[-1, 1]]^{10} \). The simulator function \( \bar{f}(\bar{p}) \) is computed by the following algorithm:
Input: $\vec{p}$

For $i := 1$ to $10$ do $\delta_i = \sqrt{(x_i - p_1)^2 + (y_i - p_2)^2}$;

Sort the reals $\delta_i$ and store them into the vector $\vec{f}$;

Output: $\vec{f}$.

For $\vec{R}_0 = ([{-1}, 10], [-1, 10])$ and $\varepsilon = 0.04$, SIVIA brackets the feasible set $\mathcal{S}$ as represented on Figure 2, in less than 5 seconds on a PC DX4-100 computer.

Possible location for Table 1

Possible location for Figure 2

**Test case 3:** In a manufacturing system, 10 identical parts are given to the input. The input dater vector is given for example by $\vec{u} = (1, 1, 1, 3, 5, 9, 9, 15, 16, 16)^T$. These 10 parts have to be manufactured by two machines $\mathcal{M}_1$ and $\mathcal{M}_2$. The loading of a part in a machine occurs only when this machine is free. The working time are $p_1$ for $\mathcal{M}_1$ and $p_2$ for $\mathcal{M}_2$.

When a part is available, the machine that is chosen to deal with this part is the one that can complete it as soon as possible. The times at which the parts are manufactured are stored in the dater vector $\vec{f}$.

The following algorithm computes the output dater vector. The real numbers $h_1$ and $h_2$ denote times at which $\mathcal{M}_1$ and $\mathcal{M}_2$ are available.
**Input:** $p_1$ and $p_2$;

1. $h_1 := 0; \ h_2 := 0$
2. For $i := 1$ to $10$ do
3. \hspace{1em} $z_1 := \max(h_1, u_i) + p_1; \ z_2 := \max(h_2, u_i) + p_2$
4. \hspace{1em} If $z_1 \leq z_2$, \hspace{1em} \hspace{1em} \hspace{1em} \hspace{1em} \hspace{1em} \hspace{1em} $f_i := z_1; \ h_1 := z_1$
5. \hspace{1em} Else $f_i := z_2; \ h_2 := z_2$
6. EndFor

**Output:** $\vec{f} = (f_1, \ldots, f_{10})$;

Line 1: At the beginning, $M_1$ and $M_2$ are free at time 0. Line 3: If the part $i$ is available at time $u_i$, if $M_1$ is free at time $h_1$, and if the working time of $M_1$ is $p_1$, then $M_1$ can complete the part at time $z_1$. Idem for $M_2$. Line 4: If $M_1$ can complete the part $i$ before $M_2$, $M_1$ is selected. The part will be completed at time $f_i$ and $M_1$ will then be free at time $h_1$.

Unfortunately, to the best of our knowledge, because of the if statement, no available methodologies exists to derive an inclusion function for $\vec{f}(\vec{p})$. The algorithm SIVIA is thus unable to deal with this last test case.

**IV. Conclusion**

Problems involved in DES are generally nonlinear, nonconvex and nondifferentiable so that classical methods often fail to give reliable results. As shown in this paper, interval analysis makes it possible to deal with such problems in a global and guaranteed way thanks to the fundamental notion of inclusion function that can be computed for many algorithms involving sorting routines and nonlinear function such as max, min, ln, ... 

As an illustration, the problem of characterizing the set of all parameter vectors that are consistent with all collected data, in a bounded-error context, has been considered. This
problem can be cast into a set-inversion framework, where the set of all acceptable output vectors has to be inverted by the simulator function. For this purpose, an interval-based algorithm SIVIA has been presented. SIVIA has treated two illustrative test cases for which, to the best of our knowledge, no other methods existed in the literature that could lead to comparable results. The third test-case was not treated because no inclusion function for the simulator function were available.

The main limitation of our approach is that for a large class of TDES, an inclusion function for the algorithm to be inverted is difficult to obtain and adapted methods should be developed to obtain them.
